Abstract. In an economy with private information, we introduce the notion of objects of choice as lists of bundles out of which the market selects one for delivery. This leads to an extension of the model of Arrow-Debreu that is used to study *ex-ante* trade with private state verification. Under the assumption that agents are *prudent*, equilibrium is characterized by the fact that agents consume bundles with the same utility in states that they do not distinguish. This is a weaker condition than the restriction of equal consumption used in Radner (1968), therefore, some “*no trade*” situations are avoided, efficiency of trade increases, and welfare improves in the sense of Pareto.

Keywords: General equilibrium, Private information, Radner equilibrium, Differential information, Incomplete information, Knightian uncertainty, Ambiguity, Contract Theory, Uncertain delivery, Lists of bundles.

JEL Classification Numbers: C62, D51, D82.

1 Introduction

Uncertainty and private information are crucial in modern economies. Agents know that their decisions can lead to different outcomes, depending on the decisions of others, and on the state of the environment. The complexity associated with these issues is such that it cannot be completely captured by any simple model. A realistic goal is to find simple models that give enlightening, although partial, descriptions.

In general equilibrium theory, several proposals have been made regarding the introduction of private information. We restrict our analysis to a model in which private information is represented by a partition of a finite set of states of nature.¹ Agents trade before knowing in which set of their partition lies the actual state of nature (trade is made *ex ante* under private and imperfect state verification). This is a usual setting in the contract theory literature, particularly the notion of events that are ‘observable, but not verifiable’, and the receiving of private information after a contract has been signed - which is termed ‘hidden knowledge’ (Tirole, 1999).

In this context, the seminal contribution was made by Radner (1968), who restricted agents to consume the same in states of nature that they did not distinguish. With this condition, the model of Arrow and Debreu (1954) could be reinterpreted in a way that took into account each agent’s private information.²

Many useful and incentive compatible contracts are excluded by this restriction. For example, the consumption of an agent that sells an option may not be the same in states that the agent does not distinguish, because it depends on whether another agent exercises the option or not. Consider the trading of a particular kind of options: an agent that buys a bundle A and sells an option to get A

¹Following the terminology of Laffont (1986), information is in the form of *fixed information structures without noise*.

²If trade occurred in the *interim* stage, that is, after agents receive their private information, knowledge of the state space could allow agents to infer the actual state of nature from observation of prices, and arrive at a *rational expectations equilibrium* (Radner, 1979).

for B , is sure of consuming either A or B (depending on whether the option is exercised or not). This is what we call **uncertain delivery**: the agent has a **list** of bundles and is certain of consuming one of the bundles in the list.

From the perspective of the agent, a combination of classical state-contingent bundles, options of a particular kind, and contracts with default of a particular kind, can be translated into a list for uncertain delivery. The list specifies a finite set of possible resulting consumption bundles, with the selection of the actual bundle to be consumed being made by the market.

For a general treatment of contracts in a private information setting, the notion of incentive compatibility is needed, as Holmström and Myerson (1983) made clear. The consideration of all incentive compatible trade contracts establishes the attainable levels of welfare in the presence of private information. The task of studying general equilibrium with incentive compatibility constraints was taken up by Prescott and Townsend (1984a, 1984b), who used linear utility functions to avoid the non-convexities of the incentive compatible set.³

A downside of taking the set of incentive compatible contracts as a foundation lies in the very demanding informational requirements about the economy and its whole state space. How can an agent know that a contract on the table is incentive compatible? This would be possible in a context of imperfect information, with agents knowing the space of states, or being able to transform the economy with incomplete information into one of imperfect information (Harsanyi, 1967). With complete information, this approach is the adequate. But in some contexts, as in large market interactions, complete information may be considered a strong requirement.⁴

Going back to the contribution of Radner (1968), we can observe that the drastic

³This is consistent with maximization of expected utility in a consumption space that is the set of lotteries over a maximum of n possible bundles.

⁴The same information requirements are needed for a *rational expectations equilibrium* (Radner, 1979) to arise. The whole economy has to be common information, otherwise agents could not be able to infer the information of all the other agents in the economy simply by observing equilibrium prices.

‘measurability’ restriction avoids all these complications. There is no need for common information assumptions. Furthermore, incentive compatibility is not an issue, because a contract that promises delivery of the same bundle in states of nature that the agent does not distinguish is necessarily incentive compatible. The agent cannot be tricked and receive a different bundle than the one that corresponds to the actual state of nature. So, in the economy of Radner (1968), agents do not need any knowledge about the space of states of the economy. It can be assumed that they see a set of their partition of information as a single state.⁵ In our paper, this can also be assumed. Agents can be restricted to knowledge of their own characteristics (that is, knowledge of their own possible types), being ignorant about the characteristics of the other agents in the economy.

In the economy with uncertain delivery, agents buy the same lists for uncertain delivery in states that they do not distinguish. Therefore, the impossibility of observing the state of nature does not raise issues of incentive compatibility. In states that agents do not distinguish, their ‘rights’ are the same: to receive one of the bundles in the list. This is not a ‘measurability’ restriction on the possible trades, but a way to formalize the consequences of incomplete state verification.

Consider an agent that buys A1 (delivery of good A in state 1) and B2, but is not able to verify whether the true state is 1 or 2. The agent may receive A1 and B2, but may also receive A1 and B1, A2 and B1 or A2 and B2. That is, the agent receives ‘good A or good B’ in states ‘1 and 2’. Observe that the agent receives (A or B)1 and (A or B)2. This is the meaning of the lists and of the usually called ‘measurability restriction’. An agent can buy something that is not ‘measurable’, but, in practice, the ‘set of alternatives that may be delivered’ is measurable - in this case it is ‘A or B’ in both states that the agent does not distinguish.

Contracts for uncertain delivery are strongly related to incentive compatible contracts. In a classical state-contingent contract, a state is announced and the corresponding net trade is made. The contract is incentive compatible if it is in the self-interest of the agents to announce the states truthfully. With contracts

⁵In the literature, several terms are used to describe the kind of uncertainty between states which cannot be reduced to a prior probability assessment: *Knightian uncertainty*, *true uncertainty*, *irreducible uncertainty*, *ambiguity* and *ignorance*.

for uncertain delivery, states are not even announced. Agents simply decide which net trade to make. In spite of this difference, an incentive compatible contract that delivers A in state 1 and B in state 2 results in the same consumption as a list that delivers $(A \vee B)$ in both states 1 and 2. Since the former contract is incentive compatible, the same incentives imply that the list also delivers A in state 1 and B in state 2. For any incentive compatible trade, there is a “list” that results in the same trade.

We can assume that agents do not have any additional information about the state space, and that they cannot find out whether some state-contingent delivery is incentive compatible or not. The economy is not common information, agents only know their own characteristics and the prevailing prices. They do not know the endowments and preferences of the others, and aren’t able to figure them out. This irreducible incompleteness of information will lead us to an alternative equilibrium concept. Naturally, the outcome should have a lower welfare level relatively to the model in which the economy is common information.

There is a recent literature on decision under ambiguity.⁶ For our purposes it is enough to refer the work of Gilboa and Schmeidler (1989), who axiomatized *maxmin* expected utility with multiple priors. The general idea is that agents cannot reduce all their uncertainty into risk, and end up with a set of plausible priors instead of a single one. In this setting, they evaluate expected utility using the worst of the priors.⁷

We study economies with trade *ex ante* under incomplete and private state verification using the concept of uncertain delivery. The solution that we propose is a *prudent expectations equilibrium*: with objects of choice being lists of bundles out of which the market selects one for delivery, agents expect to receive the worst of the possibilities specified in a list. The model of Arrow-Debreu is reinterpreted to cover this situation, therefore, many classical results still hold: existence of core and equilibrium, core convergence, continuity properties, etc.

⁶Following an early work by Arrow and Hurwicz (1972).

⁷This corresponds to infinite uncertainty aversion in the more general decision making model under ambiguity of Klibanoff, Marinacci and Mukerji (2005).

Prudence, or, ambiguity aversion, leads agents to select bundles with the same utility for consumption in states that they do not distinguish, and therefore to obtain the same utility in states of nature that they do not distinguish.⁸ It is a weaker restriction than equal consumption, therefore, the efficiency of trade and welfare are improved relatively to the model of Radner (1968). On the other hand, the welfare of an incentive compatible solution isn't reached. This gives an indication of the welfare cost of ambiguity.

The paper is organized as follows: in section 2 we introduce the concept of uncertain delivery and its relation with options and contracts with default; in section 3 we discuss and justify prudent preferences over lists; section 4 includes examples that motivate the paper; the model of general equilibrium with uncertain delivery is formalized in section 5 and characterized in section 6; in section 7, concepts of core in economies with uncertain delivery are introduced and commented; in section 8 we conclude the paper with some remarks.

⁸Agents actually receive the worse of the possibilities in the list (this is trivial, because all possibilities are equally good/bad in equilibrium), thus their expectations are fulfilled and we can talk about an expectational equilibrium.

2 Uncertain Delivery

The theory of general equilibrium under uncertainty has developed upon the formulation of objects of choice as contingent consumption claims (Arrow, 1953). Under this formulation, besides being defined by their physical properties and their location in space and time, commodities are also defined by the *state of nature* in which they are made available. This incorporation of uncertainty in the commodity space allows an interpretation of the Walrasian model that covers the case of uncertainty.

The Arrow-Debreu (1954) economy with uncertainty extends over two time periods. In the first period, agents know their preferences and endowments, which depend on the state of nature. In this *ex ante* stage, agents trade state-dependent endowments for state-dependent consumption goods. In the second period, the state of nature becomes public information, trade is realized, and consumption takes place.

In the presence of private information, the state of nature does not become public information. In this case, agents have to be careful when trading contingent goods. Suppose that the market offers you the following game:

“I will toss a coin. If the result is heads, you receive a bicycle; if it is tails, you don’t receive anything.”

If it is common information that the agent does not observe the coin toss, this contingent good has no value because the market is able to report heads and avoid delivery.

Assuming that agents only trade goods contingent on events that they can observe, Radner (1968) extended the model of Arrow and Debreu to the case of private information.⁹ This restriction implies incentive compatibility. Whatever

⁹Private information was introduced in the model simply by restricting the agent’s consumption set to values that imply equal consumption in states of nature that the agent does not distinguish. Technically, consumption must be P_i -measurable, where P_i is the σ -algebra that represents the private information of agent i .

the state of nature that occurs, agents are always sure about the bundle that will be delivered to them, so they can never be deceived.

But an agent may accept delivery of different bundles in states of nature that she does not distinguish. Suppose that the market offers a different game:

“I will toss a coin. If the result is heads, you receive a blue bicycle; if it is tails, you receive a red bicycle.”

Even if it is common information that the agent does not observe the coin toss, this is a valuable *uncertain* contingent good, because the delivery of a “*bicycle*” is guaranteed.

In our model, agents are allowed to buy “*contracts for uncertain delivery*” or “*lists*”, which specify a list of bundles out of which the market selects one for delivery. These contracts can also be contingent upon events.¹⁰ A “*contingent list*” gives the right to one of the bundles in the list if the specified contingency occurs.

These objects of choice are more general than contingent consumption claims.¹¹ Actually, the possible trades are, in a certain sense, the incentive compatible trades. To see this, consider an incentive compatible contract delivering x_1 in state ω_1 and x_2 in state ω_2 . This contract can be substituted by a contract for uncertain delivery of $(x_1 \vee x_2)$. The fact that the former contract is incentive compatible implies that the contract for uncertain delivery also delivers x_1 in ω_1 and x_2 in ω_2 .

Included in the definition of contract for uncertain delivery is the trading of a particular kind of options. Suppose that an agent buys a bundle x while selling an option to make a net trade $y - x$. The final consumption bundle will be x if the “market” does not exercise the option, and y if the option is exercised. The corresponding list for uncertain delivery can be written as $(x \vee y)$.

¹⁰An ‘event’ is a set of states of nature. It is said to ‘occur’ if the actual state of nature belongs to the set.

¹¹Notice that contracts for contingent delivery (Arrow, 1953) can be seen as “*contracts for uncertain delivery*” with lists of only one element.

The trading of a particular kind of contracts with default clauses is also covered by this definition. Suppose that an agent buys the bundle x , but gives the market the possibility of defaulting the contract and delivering bundle y as a penalty. The resulting uncertain bundle is, again, $(x \vee y)$.

An agent that trades state-contingent bundles, this particular kind of options, and this particular kind of contracts with default, can calculate the list of possible outcomes.¹² The actual outcome will depend on the choice of the market. In this setting, the objects of choice are lists for uncertain delivery.

¹²We put a finite bound, K , on the number of possible outcomes in order to work in a finite dimensional space.

3 Prudent preferences

With agents selecting among uncertain bundles, it is necessary to extend the domain in which preferences are defined. What is the utility of receiving “ x_1 or x_2 ”? In this paper we use *maxmin* preferences (Gilboa and Schmeidler, 1989).¹³ Agents attribute to the uncertain bundle $(x_1 \vee x_2)$ the utility of the worst possibility:

$$U(x_1 \vee x_2) = \min\{u(x_1), u(x_2)\}.$$

Contingent bundles which are constant in states that the agent does not distinguish can be seen as contingent lists with only one element. In this case, prudent utility is clearly equal to the usual expected utility. This formulation of prudent utility extends the utility functions to a domain that also includes lists, preserving the values in the original consumption space.

The motivation for the use of prudent preferences is essentially the same of the literature on decision making under ambiguity (Schmeidler, 1989). Agents are assumed to be completely ignorant with respect to the differences between states that their information structures do not allow them to distinguish. Therefore, they cannot reduce their uncertainty about which of the bundles in the list will be delivered into a simple prior.

Consider, for example, an agent going to the market and being offered a “bicycle or car”. The agent clearly will expect to receive the “bicycle” with (at least) almost certainty. Given their ignorance of the state space, agents may behave defensively, expecting the worst outcome in order to avoid being deceived by the market.¹⁴

If the bundles are actually portfolios that give a money return, then it is realistic for the agents to expect that the worst possibility is going to be delivered. Suppose

¹³These preferences can also be seen as a degenerate case of Choquet expected utilities (Schmeidler, 1989) since the whole weight is placed on the worst possible utility.

¹⁴If the good defined as a “bicycle or car” had a price higher than the good defined as a “bicycle”, then an arbitrageur could earn some profit by buying “bicycles” and selling “bicycles or cars”.

that there is an additional round of trade. Agents evaluate the utility of bundles (portfolios) by their value in the second round of trade. The market (seller) does exactly the same valuation. In this case, the market always delivers the bundle with the lowest (*ex-post*) value, so this worst bundle is what the buyer always receives.

Axiomatization

The following analysis resembles the work of Arrow and Hurwicz (1972) on optimality criteria for decision making under ignorance. By “ignorance” it is meant that the agent has no prior probabilities on the occurrence of different states, perceiving them as a single state.

Only the “*prudent preferences*” satisfy the two assumptions made precise below. The first is a kind of independence, and the second is related to realism. According to the first, substituting one possibility in a list by another that has greater utility does not make the list less attractive.

$$(P1) \quad x_j \succeq y_j, \forall j = 1, \dots, k \Rightarrow (x_1 \vee \dots \vee x_k) \succeq (y_1 \vee \dots \vee y_k).$$

Suppose that an agent is indifferent between receiving a “blue bicycle” and a “red bicycle”. What utility should be assigned to the delivery of a “blue bicycle or red bicycle”? Some agents may prefer to know what will be delivered in the future, while others may prefer to be surprised. A corollary of *P1* is that agents are neutral with respect to surprise:

$$\forall x_1, \dots, x_k : x_1 \sim \dots \sim x_k \Rightarrow (x_1 \vee \dots \vee x_k) \sim x_1 \sim \dots \sim x_k.$$

It is easy to see that *P1* implies that the utility of a list cannot be lower than the utility of the worst possibility. Assuming that the least preferred bundle is x_1 :

$$x_j \succeq x_1, \forall j = 1, \dots, k \Rightarrow (x_1 \vee \dots \vee x_k) \succeq (x_1 \vee \dots \vee x_1) \sim x_1.$$

The second property means that an agent is indifferent between a bundle x_1 and a list with x_1 and $x_1 + a$, where $a \geq 0$. If the market keeps the contract by delivering x_1 , why would make the effort to deliver the additional a ? The agent realistically expects to receive always x_1 , and never $x_1 + a$.

$$(P2) \quad \forall x_1, \dots, x_k : x_{k+1} \geq x_k \Rightarrow (x_1 \vee \dots \vee x_k \vee x_{k+1}) \sim (x_1 \vee \dots \vee x_k).$$

To see that $P1$ and $P2$ together imply *maxmin* preferences, assume that preferences satisfy $P1$ and $P2$. Introducing an alternative such as $x_{k+1} \geq x_k$ does not increase the utility of the list, and, by $P1$, introducing an alternative that is less attractive than x_{k+1} also does not. Thus there isn't any additional alternative that increases the utility of the list.

$$\forall x_1, \dots, x_k, x_{k+1} : (x_1 \vee \dots \vee x_k \vee x_{k+1}) \preceq (x_1 \vee \dots \vee x_k).$$

Under $P1$ and $P2$, agents behave with prudence, being indifferent between the uncertain bundle and the worst possibility:

$$\begin{aligned} x_1 \preceq x_j, \forall j = 1, \dots, k &\Rightarrow (x_1 \vee \dots \vee x_k) \sim x_1 \Leftrightarrow \\ \Leftrightarrow \forall x_1, \dots, x_k : u(x_1 \vee \dots \vee x_k) &= \min_{j=1, \dots, k} u(x_j). \end{aligned}$$

4 Examples

In this section, we give two examples of trading between two agents who do not have any common information. As a result, if agents are constrained to consume the same in states that they do not distinguish, there is *no trade* in equilibrium. With *contracts for uncertain delivery*, agents can trade and, as a result, welfare improves in the sense of Pareto.

Example 1: Perfect substitutes

This economy has two agents and four commodities: “ham sandwiches”, “cheese sandwiches”, “orange juices” and “apple juices”. Sandwiches are perfect substitutes, as well as the juices. Agents want to eat and drink. Precisely, they maximize expected utility, having state-contingent preferences described by a Cobb-Douglas utility function:

$$u = (s_h + s_c)^{0.5} \cdot (j_o + j_a)^{0.5}.$$

There are four possible states of nature, $\Omega = \{\omega_1, \omega_2, \omega_3, \omega_4\}$.

- In ω_1 , agent A is endowed with two “ham sandwiches” and agent B with two “orange juices”: $e_A(\omega_1) = (2, 0, 0, 0)$ and $e_B(\omega_1) = (0, 0, 2, 0)$;
- In ω_2 , agent A is endowed with two “ham sandwiches” and agent B with two “apple juices”: $e_A(\omega_2) = (2, 0, 0, 0)$ and $e_B(\omega_2) = (0, 0, 0, 2)$;
- In ω_3 , agent A is endowed with two “cheese sandwiches” and agent B with two “orange juices”: $e_A(\omega_3) = (0, 2, 0, 0)$ and $e_B(\omega_3) = (0, 0, 2, 0)$;
- In ω_4 , agent A is endowed with two “cheese sandwiches” and agent B with two “apple juices”: $e_A(\omega_4) = (0, 2, 0, 0)$ and $e_B(\omega_4) = (0, 0, 0, 2)$.

Each agent observes only its endowments. The information partitions are:

$$P_A = \{\{\omega_1, \omega_2\}, \{\omega_3, \omega_4\}\} \text{ and } P_B = \{\{\omega_1, \omega_3\}, \{\omega_2, \omega_4\}\}.$$

Agents want to guarantee that they will eat and drink in the future. The problem is that they are unable to make trades contingent upon events (sets of states) that they observe. For example, agent A would like to consume orange juice. For consumption to be the same across undistinguished states, the delivery of orange juice must be the same in ω_1 and ω_2 and the same in ω_3 and ω_4 . This is not possible, because agent B only has orange juice in the states ω_1 and ω_3 . The same reasoning applies to each of the other commodities, so there is no trade in the economy.¹⁵

Nevertheless, contracts for uncertain delivery allow agents to guarantee future consumption of a sandwich and a juice. The agents can agree to deliver a “sandwich” for a “juice” in the second period. This constitutes a contract for uncertain delivery in which one of the agents gets the right to receive an “orange juice or apple juice”, while the other gets the right to receive a “ham sandwich or cheese sandwich”.

Delivery of an “orange juice or apple juice” may be seen as a contract with a default clause, in which the agent should deliver an “orange juice”, but may default and pay an “apple juice” as penalty. It may also be seen as the combination of a contract for the delivery of an “orange juice”, with an option to get the “orange juice” in exchange for an “apple juice”.

Since agent A is able to ensure the delivery of a sandwich and agent B is able to ensure the delivery of a juice, this contract for uncertain delivery allows them to attain the optimal outcome:

$$x_A = x_B = \begin{cases} (1, 0, 1, 0) & \text{in } \omega_1, \\ (1, 0, 0, 1) & \text{in } \omega_2, \\ (0, 1, 1, 0) & \text{in } \omega_3, \\ (0, 1, 0, 1) & \text{in } \omega_4. \end{cases}$$

Both agents obtain an utility that is equal to 1 in all states of nature. This constitutes an improvement in the sense of Pareto relatively to the Walrasian

¹⁵It should be clear that we can assume strictly positive endowments, substituting every zero for a small ϵ , and reach similar conclusions.

expectations equilibrium solution, which resulted in an utility of zero to both agents.

Example 2 - Risk sharing

Consider an economy with two agents, two goods and three states of nature. Initial endowments depend on the state of nature:

$$e_A = \begin{cases} (199, 100) & \text{in } \omega_1, \\ (1, 100) & \text{in } \{\omega_2, \omega_3\}. \end{cases} \quad e_B = \begin{cases} (1, 100) & \text{in } \{\omega_1, \omega_2\}, \\ (199, 100) & \text{in } \omega_3. \end{cases}$$

The state ω_2 has a probability of 0,2%, while ω_1 and ω_3 have a probability of 49,9%. Agents know these probabilities but there are no commonly observed events:

$$P_A = \{\{\omega_1\}, \{\omega_2, \omega_3\}\} \text{ and } P_B = \{\{\omega_1, \omega_2\}, \{\omega_3\}\}.$$

Agents want to maximize expected utility, having the same preferences in all states of nature. The marginal utility of good 1 is decreasing, while marginal utility of good 2 is constant:

$$u_A(x_1, x_2) = u_B(x_1, x_2) = 10\sqrt{x_1} + x_2.$$

Observe the symmetry in the economy: agent A wants to sell good 1 in ω_1 and to buy in $\{\omega_2, \omega_3\}$, while agent B wants to buy in $\{\omega_1, \omega_2\}$ and to sell in ω_3 .

The total resources in the economy are:

$$e_{total} = \begin{cases} (200, 200) & \text{in } \omega_1, \\ (2, 200) & \text{in } \omega_2, \\ (200, 200) & \text{in } \omega_3. \end{cases}$$

Restricting consumption to be the same in states that agents do not distinguish, Pareto improvements relatively to the initial endowments are not possible. But, as in example 1, contracts for uncertain delivery allow agents to improve their welfare.

With prudent preferences, the equilibrium allocation is:

$$x^A = \begin{cases} (100, 190) \text{ in } \omega_1, \\ (1, 100) \text{ in } \omega_2, \\ (100, 10), \omega_3. \end{cases} \quad u^A = \begin{cases} 290 \text{ in } \omega_1, \\ 110 \text{ in } \{\omega_2, \omega_3\}. \end{cases}$$

$$x^B = \begin{cases} (100, 10) \text{ in } \omega_1, \\ (1, 100) \text{ in } \omega_2, \\ (100, 190), \omega_3. \end{cases} \quad u^B = \begin{cases} 110 \text{ in } \{\omega_1, \omega_2\}, \\ 290 \text{ in } \omega_3. \end{cases}$$

Agents can obtain this allocation by trading an option. In every state of nature, each agent has the option to get 90 units of good 2 in exchange for 99 units of good 1. This is equivalent to uncertain delivery of $(99, -90)$ or $(0, 0)$. It is straightforward to see that agent A exercises the option in state 1 and agent B exercises the option in state 3.

5 General Equilibrium with Uncertain Delivery

The model of the *economy with uncertain delivery* is based on the model known as a *differential information economy*, but with a modified informational restriction. Agents have incomplete and private state verification, represented by a partition on a finite set of states of nature. As a result, if they buy different rights for delivery in states that they cannot distinguish, then they have to accept any delivery that is compatible with their information (that is, compatible with their limited ability to verify the state of nature).

It is very important to understand the meaning and impact of private information in this model. Consider an agent that buys A1 (delivery of good A in state 1) and B2, but is not able to verify whether the true state of nature is 1 or 2. As a consequence, the agent may receive A1 and B2, but may also receive A1 and B1, A2 and B1 or A2 and B2. That is, the agent receives ‘good A or good B’ in states ‘1 and 2’. Observe that the agent receives (A or B)1 and (A or B)2 - the same ‘list’ in states of nature that are not distinguished. This is the meaning of the ‘lists’ and of the usually called ‘measurability restriction’. An agent can buy something that is not ‘measurable’, but, in practice, the ‘set of alternatives that may be delivered’ is measurable - in this case it is ‘A or B’ in both states that the agent does not distinguish.

We restrict agents to select the same list for delivery in states that they do not distinguish (instead of the same bundle as in Radner (1968) and Yannelis (1991)). Technically, the list must be P_i -measurable, which does not imply that consumption is P_i -measurable.¹⁶

To get familiar with the workings of the model and with the notation that is used, consider three possible states of nature, $\Omega = \{\omega_1, \omega_2, \omega_3\}$, and an agent who does not distinguish ω_1 from ω_2 . Instead of observing prices in ω_1, ω_2 and ω_3 , it may be assumed that the the agent only observes prices for delivery in the events $\{\omega_1, \omega_2\}$ and ω_3 . In the economy with uncertain delivery, besides announcing the prices of

¹⁶In their study of implementation in differential information economies, Postlewaite and Schmeidler (1986) do not impose any measurability restriction on the outcome.

the bundles, the market also reports the prices of *lists*.¹⁷ Denote the price of the list $(x_1 \vee x_2)$ in ω_1 by $\tilde{p}_1(x_1 \vee x_2)$. It may be assumed that the agent only observes the price of $(x_1 \vee x_2)$ in the event $\{\omega_1, \omega_2\}$, that is, $\tilde{p}_1(x_1 \vee x_2) + \tilde{p}_2(x_1 \vee x_2)$.

Suppose that an agent buys the list $\tilde{x} = [(x_1 \vee x_2), (x_1 \vee x_2), x_3]$. To keep this contract for uncertain delivery, the market must deliver one of the four contingent bundles: (x_1, x_1, x_3) , (x_1, x_2, x_3) , (x_2, x_1, x_3) , (x_2, x_2, x_3) . It is as if a fictitious intermediary had to guarantee delivery of one of the alternatives. The intermediary would buy the cheapest contingent bundle satisfying the requirements of the list and deliver it to the agent. For the list to be deliverable, its price cannot be lower than the price of the cheapest alternative.

$$\tilde{p}_1(x_1 \vee x_2) + \tilde{p}_2(x_1 \vee x_2) \geq \min\{p_1 \cdot x_1, p_1 \cdot x_2\} + \min\{p_2 \cdot x_1, p_2 \cdot x_2\}.$$

The price of the list $(x_1 \vee x_2)$ in the event $\{\omega_1, \omega_2\}$ cannot be higher than the price of the cheapest alternative. If it were, there would be an opportunity for arbitrage. Another intermediary could buy the cheapest alternative and sell the list with profit. This no-profit condition prevents prices of options from being negative.¹⁸

$$\tilde{p}_1(x_1 \vee x_2) + \tilde{p}_2(x_1 \vee x_2) \leq \min\{p_1 \cdot x_1, p_1 \cdot x_2\} + \min\{p_2 \cdot x_1, p_2 \cdot x_2\}.$$

In sum, given the prices of the contingent goods, the supply curve of a list is a vertical line passing on the price of the cheapest contingent bundle satisfying the requirements of the list. The price of a list is equal to the minimum of the prices of the contingent bundles satisfying its requirements of the list. This gives a unique extension of prices from the space of goods to the space of lists. The price of the list $(x_1 \vee \dots \vee x_k)$ to be delivered in state ω_s is:

$$\tilde{p}_s(x_1 \vee \dots \vee x_k) = \min_{j=1, \dots, k} p_s \cdot x_j.$$

With this restriction on the prices of lists, it is enough to find equilibrium prices for the contingent commodities. The prices of the lists follow directly from those.

¹⁷Bundles are ‘lists’ with a single element.

¹⁸Observe that a list $(A \vee B)$ can be seen obtained by buying bundle A and selling an option to get A for B .

When an agent buys a list, the cheapest bundle satisfying the requirements of the lists plays a fundamental role. It is the bundle that chosen for delivery, and, furthermore, its price is equal to the price of the list.

Finding the bundles actually delivered by the market allows us to find equilibrium lists selected by the agents. From all the lists compatible with the given delivery, the list selected by a maximizing agent is the most preferred one, since all of them have the same price (the price of the delivered bundle).

With ‘prudent preferences’, we know that additional alternatives never increase the utility of a list. Then, the list selected for a given state can be constructed using the alternatives delivered in states that the agent does not distinguish from this state. For example, an agent may receive a consumption bundle that is not P_i -measurable, $x = (x_1, x_2, x_3)$. It can be induced that this would be the result of buying the P_i -measurable list $\tilde{x} = [(x_1 \vee x_2), (x_1 \vee x_2), x_3]$. No other list compatible with the delivery of x_i has strictly higher utility.

The Model

The economy extends over two time periods. In the first, agents trade their state-contingent endowments for state-contingent lists. In the second period agents receive (and consume) one of the bundles that corresponds to a state that they do not distinguish from the actual state of nature.

Consider a finite number of agents, commodities and states of nature. In the economy with uncertain delivery, $\mathcal{E} \equiv (e_i, u_i, P_i, q_i)_{i=1}^n$, for each agent i :

- A partition of Ω , P_i , represents the private information of the agent. Sets that belong to P_i are denoted A_i^j . The set of states of nature that agent i does not distinguish from ω_k is denoted $P_i(\omega_k)$.
- Agents assign subjective probabilities to the different elementary events that they observe. To each set $A_i^j \in P_i$ corresponds a prior probability $Pr_i(A_i^j)$, with $\sum_j Pr_i(A_i^j) = 1$.

- Preferences over consumption bundles are the same in undistinguished states, represented by the Von Neumann-Morgenstern (1944) utility functions $u_i^j : \mathbb{R}_+^l \rightarrow \mathbb{R}_+$, which are assumed to be continuous, weakly monotone and concave.
- The initial endowments are constant across undistinguished states, and strictly positive: $e_i^j \gg 0$ for all j .

The objective function, *prudent expected utility*, is:

$$\tilde{U}_i(\tilde{x}_i) = \sum_{A_i^j \in P_i} Pr_i(A_i^j) \tilde{v}_i^{A_i^j}(\tilde{x}_i^{A_i^j}) = \sum_{\omega_j \in \Omega} q_i^j \tilde{v}_i^j(\tilde{x}_i^j).$$

Knowing the bundle that the agent receives, we know that the utility of the list that the agent bought is the same. It could not be higher, because the agent evaluates the list according to the worst alternative. If it were lower, then the agent receiving x_i would not be maximizing. The agent would be better off selecting the list:

$$\tilde{x}_i^s = \bigvee_{\omega_s \in P_i(\omega_s)} x_i^s.$$

The utility of this list is the same as the bundle delivered, and has the same price (remember the equality between the prices of lists and the prices of the actually delivered bundles). Since the price and the utility of a list is equal to the price and utility of the delivered bundle, the problem of the consumer can be written on bundles instead of lists. The objective function becomes:

$$U_i(x_i) = \sum_{A_i^j \in P_i} Pr_i(A_i^j) v_i^j(x_i).$$

Prudence is incorporated in the objective function. Agent i knows that the state of nature that occurred belongs to some A_i^j , and that she has the right to receive one of the bundles x_i^s with $\omega_s \in A_i^j$. Under prudent expectations, the utility that the agent expects corresponds to the worst possibility:

$$v_i^j(x_i) = \min_{\omega_s \in A_i^j} u_i^j(x_i^s).^{19}$$

¹⁹Note that if x is equal across states that the agent does not distinguish, then prudent

From the properties of the state-dependent utility functions, u_i^j , it is shown below that the *prudent expected utility* function is also concave.

$$\begin{aligned}
U_i(\lambda x_i + (1 - \lambda)y_i) &= \sum_{A_i^j \in P_i} q_i^j v_i^j(\lambda x_i + (1 - \lambda)y_i) = \\
&= \sum_{A_i^j \in P_i} q_i^j \min_{\omega \in A_i^j} \{u_i^j(\lambda x_i(\omega) + (1 - \lambda)y_i(\omega))\} \geq \\
&\geq \sum_{A_i^j \in P_i} q_i^j \min_{\omega \in A_i^j} \{\lambda u_i^j(x_i(\omega)) + (1 - \lambda)u_i^j(y_i(\omega))\} \geq \\
&\geq \sum_{A_i^j \in P_i} q_i^j \min_{\omega \in A_i^j} \{\lambda u_i^j(x_i(\omega))\} + \sum_{A_i^j \in P_i} q_i^j \min_{\omega \in A_i^j} \{(1 - \lambda)u_i^j(y_i(\omega))\} = \\
&= \lambda \sum_{A_i^j \in P_i} q_i^j v_i^j(x_i) + (1 - \lambda) \sum_{A_i^j \in P_i} q_i^j v_i^j(y_i) = \\
&= \lambda U_i(x_i) + (1 - \lambda)U_i(y_i).
\end{aligned}$$

Therefore, the model of Arrow-Debreu can be reinterpreted to cover the case of an economy with uncertain delivery in which agents are *prudent*. The economy with uncertain delivery is equivalent to an Arrow-Debreu economy, $\mathcal{E}_{AD} \equiv (e_i, U_i)_{i=1}^n$, where, for each agent i :

- Preferences are described by an utility function, $U_i : \mathbb{R}_+^{\Omega l} \rightarrow \mathbb{R}_+$, that is continuous, weakly monotone and concave. It is defined as
$$U_i(x_i) = \sum_{A_i^j \in P_i} Pr_i(A_i^j) v_i^j(x_i) = \sum_{A_i^j \in P_i} Pr_i(A_i^j) \min_{\omega \in A_i^j} u_i^j(x_i(\omega)).$$
- The vector of initial endowments, $e_i \in \mathbb{R}_+^{\Omega l}$, is strictly positive.

With the economy formalized as an Arrow-Debreu economy, the usual definitions apply. An allocation, x , is feasible if and only if:

$$\sum x \leq \sum e \Leftrightarrow \forall \omega : \sum x(\omega) \leq \sum e(\omega).$$

We normalize the price functions to the simplex of $\mathbb{R}^{\Omega l}$, that is:

$$\Delta = \{p \in \mathbb{R}^{\Omega l} : \sum_{\omega \in \Omega} \sum_{k=1, \dots, l} p_k(\omega) = 1\}.$$

expected utility is equal to classical expected utility. If agents are perfectly informed this always occurs. With symmetric information, the transformed model is equivalent to the classical model of Arrow and Debreu (1954).

The “budget set” of agent i is given by:

$$B_i(p, e_i) = \left\{ x_i \in \mathbb{R}^{\Omega l}, \text{ such that } \sum_{\Omega} p(\omega) x_i(\omega) \leq \sum_{\Omega} p(\omega) e_i(\omega) \right\}.$$

A pair (p^*, x^*) is a *Walrasian equilibrium with prudent expectations* if p^* is a price system and $x^* = (x_1^*, \dots, x_n^*)$ is a feasible allocation such that, for every i , $x_i^* \in \mathbb{R}_+^{\Omega l}$ maximizes prudent expected utility, U_i , on $B_i(p^*, e_i)$.

Private information was introduced in the model of Arrow and Debreu by a transformation of the preferences. This transformation preserves the properties of continuity, weak monotonicity and concaveness. Therefore, several classical results still hold: existence of core and Walrasian equilibrium, core convergence, continuity properties, etc.²⁰

The following theorem can be stated without proof.

Theorem 1 *There exists a Walrasian equilibrium with prudent expectations.*

As seen before, from the equilibrium defined on allocations, (x^*, p^*) , we can determine the equilibrium defined on the space of lists, $(\tilde{x}^*, \tilde{p}^*)$.

²⁰This framework also allows the analysis of continuity properties of equilibrium with respect to information as a problem of continuity with respect to preferences, which was settled by Hildenbrand and Mertens (1972).

6 Characteristics of Equilibrium

Utility is P_i -measurable

In this extended Arrow-Debreu model, equilibrium allocations are characterized by the fact that in states of nature that an agent does not distinguish, the utility of the delivered bundles tends to be equal. Instead of imposing consumption to be P_i -measurable, as Radner (1968) and Yannelis (1991), we see a weaker restriction of P_i -measurable utility arising naturally.

If equilibrium prices of the contingent commodities aren't strictly positive, then the utility of some equilibrium allocations may differ across undistinguished states. But we can refine the equilibrium set by removing a *free* component of *excess supply*. With the same equilibrium prices, the resulting equilibrium allocations have P_i -measurable utility. The following results make this precise.

Theorem 2 *Let (x^*, p^*) be a Walrasian equilibrium with prudent expectations. Then, for each agent i , $x_i^* = y_i^* + z_i$, with y_i^* having the same utility in states that the agent does not distinguish, and z_i being “free”. Precisely:*

$$y_i^* \in \mathbb{R}_+^{\Omega_l} \text{ and such that: } \omega' \in P_i(\omega) \Rightarrow u_i^\omega(y_i^*(\omega)) = u_i^{\omega'}(y_i^*(\omega')).$$

$$z_i \in \mathbb{R}_+^{\Omega_l} \text{ and such that: } p^* \cdot z_i = 0.$$

Proof. Recall that for any $\omega' \in P_i(\omega)$, preferences are the same: $u_i^\omega = u_i^{\omega'}$. Now suppose that for some $\omega' \in P_i(\omega)$, we have different utilities, that is: $u_i^\omega(x_i^*(\omega)) > u_i^\omega(x_i^*(\omega'))$. Then, there exists some $\delta < 1$ such that $u_i^\omega(\delta \cdot x_i^*(\omega)) = u_i^\omega(x_i^*(\omega'))$. Whenever this occurs, modify the allocation accordingly to obtain $y_i^* \leq x_i^*$. This allocation has P_i -measurable utility. If y_i^* belongs to the interior of the budget set, there exists a positive ϵ such that the allocation $(1 + \epsilon) \cdot y_i^*$ belongs to the budget set and has higher utility than x_i^* . In this case, x^* would not be an equilibrium allocation, and we would have a contradiction. Therefore, y_i^* is not in the interior of the budget set, that is: $z_i = x_i^* - y_i^*$ is such that $p^* \cdot z_i = 0$. QED

With agents obtaining the same utility in states that they do not distinguish, *prudent expected utility* is equal to expected utility, for any prior probabilities

over states of nature consistent with the given prior probabilities over observed events.

$$\sum_{A_i^j \in P_i} Pr_i(A_i^j) \min_{\omega \in A_i^j} u_i^j(x_i(\omega)) = \sum_{\omega_s \in \Omega} q_i^s u_i^s(x_i^s).$$

The pair (y^*, p^*) is also a *Walrasian equilibrium with prudent expectations*. But, since y^* gives the same utility in states that agents do not distinguish, the prudent behavior is not shown to have been unjustified. It never happens that an agent was expecting the worst and got something better. Prudent expectations are, in a certain sense, self-fulfilled. This constitutes a natural refinement of the concept of equilibrium.

A pair (y^*, p^*) is a “*prudent expectations equilibrium*” if p^* is a price system and $y^* = (y_1^*, \dots, y_n^*)$ is a feasible allocation such that, for every i , $y_i^* \in \mathbb{R}_+^{\Omega_i}$ maximizes U_i on $B_i(p^*, e_i)$ with $u_i(y_i^*)$ being P_i -measurable.

Corollary 1 *Given any Walrasian equilibrium with prudent expectations, (x^*, p^*) , there exists a prudent expectations equilibrium, (y^*, p^*) under the same price system $(y^*$ as defined in Theorem 1).*

Proof. The allocation y^* has the same prudent expected utilities as the equilibrium allocation x^* : $U_i(y^*) = U_i(x^*)$, for all i . Under the price system p^* , both allocations cost the same: $p^* \cdot y_i^* = p^* \cdot x_i^*$, for all i . Thus, y^* is also allowed by each agent’s budget restriction, and maximizes utility. Furthermore, since $y^* \leq x^*$, y^* is feasible. QED

An important consequence is the existence of equilibrium allocations with P_i -measurable utility. If instead of restricting agents to consume the same in states that they do not distinguish, we restrict them to consume bundles with the same utility, equilibrium existence is guaranteed.

Corollary 2 *There exists a prudent expectations equilibrium.*

There exists a Walrasian equilibrium of the Arrow-Debreu economy, so this is an obvious consequence of Corollary 1.

From Theorem 2, it is straightforward that if the contingent commodities have strictly positive prices, $p^* \gg 0$, then $z = 0$ and $x^* = y^*$. That is, all *Walrasian equilibria with prudent expectations* have P_i -measurable utility. A condition that guarantees strict positivity of the prices of the contingent commodities is sufficient to guarantee that all Walrasian equilibria with prudent expectations are *prudent expectations equilibria*. For example, if every state is observed by at least one agent.

Measurability implies incentive compatibility

A measurability restriction is still present. In states of nature that agents do not distinguish, they are entitled to receive the same lists. The impossibility of observing the state of nature is not a problem. The agent does not fear being “tricked”, because the rights are the same in states that the agent does not distinguish: to receive one of the bundles in the list.

In sum, the consideration of contracts for uncertain delivery allows us to relax in a natural way the measurability assumption, while preserving incentive compatibility. This enlarges the space of allocations, improving the efficiency of exchange, relatively to economies in which consumption has to be measurable with respect to private information.

Welfare improves

Compared with measurable consumption, measurable utility is less restrictive, as it allows agents to select different consumption bundles in states that they do not distinguish. As a result, they take advantage of the variations in prices across these states. The following theorem describes this and confirms that the cheapest bundle is chosen for delivery.

Theorem 3 *Let (x^*, p^*) be a Walrasian equilibrium with prudent expectations.*

$$\omega' \in P_i(\omega) \Rightarrow p^*(\omega) \cdot x_i^*(\omega) \leq p^*(\omega) \cdot x_i^*(\omega').$$

Proof. Suppose that for some $\omega' \in P_i(\omega)$, we had $p^*(\omega) \cdot x_i^*(\omega) > p^*(\omega) \cdot x_i^*(\omega')$. Designate by y_i a modified bundle with $y_i^*(\omega) = x_i^*(\omega')$ being the only difference relatively to x_i^* . This bundle has the same utility and allows the agent to retain some income. There exists a positive ϵ such that $(1 + \epsilon) \cdot y_i$ belongs to the budget set and has higher utility than x_i^* . Contradiction! QED

In spite of the penalization implied by prudence, *prudent expected utility* is higher in the sense of Pareto than that which is attainable under the classical restriction of equal consumption in states of nature that are not distinguished.

Theorem 4 *Let (x^*, p^*) be an equilibrium in the sense of Radner (1968). There are Pareto optima of the economy with uncertain delivery, z , such that $U_i(z_i) \geq U_i(x_i^*)$, for every agent. The improvement may be strict (see section 3).*

Proof. The proof is straightforward. If (x^*, p^*) is an equilibrium in the sense of Radner (1968), the allocation x^* is still feasible in the economy with prudent expectations. QED

From this result it does not follow that a *prudent expectations equilibrium* represents a Pareto-improvement relatively to the Walrasian expectations equilibrium. For example, a perfectly informed agent has no interest in uncertain delivery, and the change in equilibrium prices associated with the introduction of uncertain delivery may imply a decrease in the utility of this agent.

Ex post efficiency

In this model, trade was made *ex ante*, that is, before agents received their information. But what happens if, after receiving their equilibrium bundles, agents are allowed to trade again?

If equilibrium prices are strictly positive, then the equilibrium allocation is *ex post* efficient. This means that, for any given state of nature, there is no allocation that Pareto-improves the state-contingent prudent expectations equilibrium allocation. The reopening of markets has no effect. There is *no trade*.

Theorem 5 *Let (x^*, p^*) be a prudent expectations equilibrium.*

If prices are strictly positive, $p^ \gg 0$, then every state-contingent allocation, $x^*(\omega)$, is Pareto-efficient.*

Proof. Suppose that there exists a feasible $y(\omega)$ that weakly dominates $x^*(\omega)$:

$$\forall j : y_j(\omega) \succeq_{j,\omega} x_j^*(\omega), \quad \text{and} \quad \exists i : y_i(\omega) \succ_{i,\omega} x_i^*(\omega).$$

From continuity, we know that there exists a small $\epsilon > 0$ such that:

$$\exists i : (1 - \epsilon)y_i(\omega) \succ_{i,\omega} x_i^*(\omega).$$

Redistribute the wealth, $\epsilon p^*(\omega) \cdot y_i(\omega)$, among all the other state-contingent bundles, and construct an alternative to x_i^* as follows:

$$x'_i = ((1 + \epsilon_2)x_i^*(1), (1 + \epsilon_2)x_i^*(2), \dots, (1 - \epsilon)y_i(\omega), \dots).$$

Observe that, clearly: $x'_i \succ_i x_i^*$. This implies that: $p^* \cdot x'_i > p^* \cdot x_i^*$.

In state ω , all the other agents are not worse off with $y_j(\omega)$ than with $x_j^*(\omega)$.

Again, by a continuity argument, we know that:

$$\forall j \neq i : p^*(\omega) \cdot y'_j(\omega) = p^*(\omega) \cdot x_j^*(\omega).$$

Construct alternatives to x_j^* as follows:

$$x'_j = (x_j^*(1), x_j^*(2), \dots, y_j(\omega), \dots), \quad \forall j \neq i.$$

For all $j \neq i$: $x'_j \succ_j x_j^*$. Since x^* is an equilibrium: $p^* \cdot x'_j \geq p^* \cdot x_j^*$, $\forall j \neq i$.

Summing over agents, we have:

$$\sum_{j=1}^n p^* \cdot x'_j > \sum_{j=1}^n p^* \cdot x_j^* = \sum_{j=1}^n p^* \cdot e_j.$$

An inequality that implies that x' is not feasible, which in turn implies that $y(\omega)$ is not feasible. QED²¹

²¹We proved this result while working with Nuno Gouveia.

7 Cooperative Solutions: the Prudent Cores

In a cooperative setting it seems more difficult to justify that agents cannot reach the incentive compatible solution. Again, in a context of Knightian uncertainty a solution based on prudence and uncertain delivery can make sense. Conceptually, it may be placed between the *private core* (Yannelis, 1991) and the incentive compatible core.

Restricting our analysis to the case of *prudent expectations*, the core concept follows from the analysis in section 5. The economy with uncertain delivery and prudent expectations was formalized as an Arrow-Debreu economy. The core of this Arrow-Debreu economy is the “*prudent core*”.

A coalition $S \subseteq N$ “*prudently blocks*” an allocation x if there exists $(y_i)_{i \in S}$ such that: $\sum_{i \in S} y_i \leq \sum_{i \in S} e_i$ and $U_i(y_i) > U_i(x_i)$ for every $i \in S$, where U_i is the prudent expected utility of agent i .

The “*prudent core*” is the set of all feasible allocations which are not *prudently blocked* by any coalition. Although coalitions of agents are formed, information is not shared between them. The *prudent expected utility* is based only on each agent’s private information.

The *prudent core* is similar to a private core in which measurable utility is required instead of measurable consumption. An allocation without P_i -measurable utility may belong to the *prudent core*, but then there exists another allocation with the same utility for every agent, which has P_i -measurable utility and requires less resources.

Theorem 6 *Let $x \in PC(\mathcal{E})$. There exists some $x' \in PC(\mathcal{E})$ s.t., $\forall i = 1, \dots, n$:*

- a) $x'_i \leq x_i$;
- b) $U_i(x'_i) = U_i(x_i)$;
- c) $u_i(x'_i)$ is P_i -measurable.

Proof. If $u_i(x_i)$ isn't P_i -measurable, we can multiply the $x_i(\omega)$ that have higher utilities in each element of P_i by a factor smaller than 1 to obtain a modified allocation with measurable utility. These higher utilities are not taken into account in the calculation of prudent expected utility, because only the worst outcome is considered. Therefore, expected utility remains unchanged and this allocation satisfies $x'_i \leq x_i$. QED

Even being penalized by the prudence, allocations in the *prudent core* dominate, in the sense of Pareto, those in the *private core* (Yannelis, 1991). The latter are always feasible in the economy with uncertain delivery, while the converse is not true.

It is also possible to define a “*prudent coarse core*” and a “*prudent fine core*”. In the *prudent coarse core*, prudence is based on common information.

A coalition $S \subseteq N$ *strongly prudently blocks* an allocation x if there exists $(y_i)_{i \in S}$ such that: $\sum_{i \in S} y_i \leq \sum_{i \in S} e_i$ and $U_{i,S}^s(y_i) > U_{i,S}^s(x_i)$ for every $i \in S$, where $U_{i,S}^s$ is the “*strongly S-prudent expected utility*” of agent i in the coalition S . The *interim* utility for agent i in coalition S is calculated using the minimum utility across states that the coalition cannot distinguish using only the common information among the members.

Analogously, the *prudent fine core* is based on pooled information.

A coalition $S \subseteq N$ *weakly prudently blocks* an allocation x if there exists $(y_i)_{i \in S}$ such that: $\sum_{i \in S} y_i \leq \sum_{i \in S} e_i$ and $U_{i,S}^w(y_i) > U_{i,S}^w(x_i)$ for every $i \in S$, where $U_{i,S}^w$ is the “*weakly S-prudent expected utility*” of agent i in the coalition S . The interim utility for agent i in coalition S is calculated using the minimum utility across states that the coalition cannot distinguish using the pooled information of its members.

In any case, welfare is improved in the prudent cores with respect to the definitions in which P_i -measurability is required. On the other hand, the welfare of the incentive compatible core cannot be reached in general.

8 Concluding Remarks

In the presence of private information in the form of incomplete state verification, general equilibrium theory in lines of the article of Radner (1968) cannot cope with widely used contracts, like options and contracts with default. In this paper, objects of choice are lists of bundles out of which the market selects one for delivery. This notion encompasses that of objects of choice as contingent consumption claims (Arrow, 1953), allowing the study of more complex trade environments.

Under the assumption that agents have an extremely defensive behavior, the model of Arrow-Debreu can be reinterpreted to cover this situation. Therefore, many classical results still hold: existence of core and equilibrium, core convergence, continuity properties, etc. Expecting to receive the worst of the possibilities contracted, agents select bundles with the same utility for consumption in states that they do not distinguish. This improves welfare relatively to allocations with measurable consumption.²²

This equilibrium notion based on prudent behavior does not require agents to have any information about the characteristics of the other agents. This is the fundamental advantage relatively to the approach based on incentive compatibility. It is liable to criticism in contexts where agents have some information about the characteristics of others and could use it to construct their expectations, or in other settings in which cooperation is plausible.

While an intuition for the concept of rational expectations equilibrium was the idea that “*agents cannot be fooled*”, in the prudent expectations equilibrium it is the market that cannot be fooled. Agents use a rule of thumb which is related to Murphy’s law: “*if anything can go wrong, it will*”.

²²We have work in progress (2006) seeking to relax the assumption of “prudent” behavior. Naturally, with the consideration of different expectations, the result of measurable utility will no longer be true.

Whether the agents know or not the state space of the economy is an important issue for the comparison between the two concepts. In this paper, agents do not have information about the state space and therefore cannot evaluate whether a contract is incentive compatible or not. As a result, their welfare falls short to that attained when all the possible incentive compatible trades are considered.

Agents with rational expectations know the space of states and are able to calculate correctly the probability of receiving each of the bundles in a list. But real economic agents follow simple rules of decision, instead of making huge amounts of calculations (Tversky and Kahneman, 1974). This further justifies the study of equilibrium with agents constructing expectations in a simple way.
